Christian Lécot, David Munger, and Bruno Tuffin

## Markov Chain Setting

A Markov chain with state space $\mathcal{X}$ evolves as

$$
X_{0}=x_{0}, \quad X_{j}=\varphi_{j}\left(X_{j-1}, \mathbf{U}_{j}\right), j \geq 1
$$

where the $\mathbf{U}_{j}$ are i.i.d. uniform r.v.'s over $(0,1)^{d}$.

Payoff (or cost) function:

$$
Y=\sum_{j=1}^{\tau} g_{j}\left(X_{j}\right)
$$

for some fixed time horizon $\tau$.

## Markov Chain Setting

A Markov chain with state space $\mathcal{X}$ evolves as

$$
X_{0}=x_{0}, \quad X_{j}=\varphi_{j}\left(X_{j-1}, \mathbf{U}_{j}\right), j \geq 1
$$

where the $\mathbf{U}_{j}$ are i.i.d. uniform r.v.'s over $(0,1)^{d}$.

Payoff (or cost) function:

$$
Y=\sum_{j=1}^{\tau} g_{j}\left(X_{j}\right)
$$

for some fixed time horizon $\tau$.
We may want to estimate

$$
\mu=\mathbb{E}[Y]
$$

or some other functional of $Y$, or perhaps the entire distribution of $Y$.

## Ordinary Monte Carlo simulation

 For $i=0, \ldots, n-1$, generate $X_{i, j}=\varphi_{j}\left(X_{i, j-1}, \mathbf{U}_{i, j}\right), j=1, \ldots, \tau$, where the $\mathbf{U}_{i, j}$ 's are i.i.d. $\mathbf{U}(0,1)^{d}$. Estimate $\mu$ by$$
\hat{\mu}_{n}=\frac{1}{n} \sum_{i=0}^{n-1} \sum_{j=1}^{\tau} g_{j}\left(X_{i, j}\right)=\frac{1}{n} \sum_{i=0}^{n-1} Y_{i}
$$

$$
\mathbb{E}\left[\hat{\mu}_{n}\right]=\mu \text { and } \operatorname{Var}\left[\hat{\mu}_{n}\right]=\frac{1}{n} \operatorname{Var}\left[Y_{i}\right]=\mathcal{O}\left(n^{-1}\right)
$$

The width of a confidence interval on $\mu$ converges as $\mathcal{O}\left(n^{-1 / 2}\right)$.
That is, for each additional digit of accuracy, one must multiply $n$ by 100 .

## Ordinary Monte Carlo simulation

For $i=0, \ldots, n-1$, generate $X_{i, j}=\varphi_{j}\left(X_{i, j-1}, \mathbf{U}_{i, j}\right), j=1, \ldots, \tau$, where the $\mathbf{U}_{i, j}$ 's are i.i.d. $\mathbf{U}(0,1)^{d}$. Estimate $\mu$ by

$$
\hat{\mu}_{n}=\frac{1}{n} \sum_{i=0}^{n-1} \sum_{j=1}^{\tau} g_{j}\left(X_{i, j}\right)=\frac{1}{n} \sum_{i=0}^{n-1} Y_{i}
$$

$$
\mathbb{E}\left[\hat{\mu}_{n}\right]=\mu \text { and } \operatorname{Var}\left[\hat{\mu}_{n}\right]=\frac{1}{n} \operatorname{Var}\left[Y_{i}\right]=\mathcal{O}\left(n^{-1}\right)
$$

The width of a confidence interval on $\mu$ converges as $\mathcal{O}\left(n^{-1 / 2}\right)$.
That is, for each additional digit of accuracy, one must multiply $n$ by 100 .
Can also estimate the distribution (density) of $Y$ by the empirical distribution of $Y_{0}, \ldots, Y_{n-1}$, or by an histogram (perhaps smoothed), or by a kernel density estimator. The mean integrated square error (MISE) for the density typically converges as $\mathcal{O}\left(n^{-2 / 3}\right)$ for an histogram and $\mathcal{O}\left(n^{-4 / 5}\right)$ for the best density estimators.

## Ordinary Monte Carlo simulation

For $i=0, \ldots, n-1$, generate $X_{i, j}=\varphi_{j}\left(X_{i, j-1}, \mathbf{U}_{i, j}\right), j=1, \ldots, \tau$, where the $\mathbf{U}_{i, j}$ 's are i.i.d. $\mathbf{U}(0,1)^{d}$. Estimate $\mu$ by

$$
\hat{\mu}_{n}=\frac{1}{n} \sum_{i=0}^{n-1} \sum_{j=1}^{\tau} g_{j}\left(X_{i, j}\right)=\frac{1}{n} \sum_{i=0}^{n-1} Y_{i}
$$

$$
\mathbb{E}\left[\hat{\mu}_{n}\right]=\mu \text { and } \operatorname{Var}\left[\hat{\mu}_{n}\right]=\frac{1}{n} \operatorname{Var}\left[Y_{i}\right]=\mathcal{O}\left(n^{-1}\right)
$$

The width of a confidence interval on $\mu$ converges as $\mathcal{O}\left(n^{-1 / 2}\right)$.
That is, for each additional digit of accuracy, one must multiply $n$ by 100 .
Can also estimate the distribution (density) of $Y$ by the empirical distribution of $Y_{0}, \ldots, Y_{n-1}$, or by an histogram (perhaps smoothed), or by a kernel density estimator. The mean integrated square error (MISE) for the density typically converges as $\mathcal{O}\left(n^{-2 / 3}\right)$ for an histogram and $\mathcal{O}\left(n^{-4 / 5}\right)$ for the best density estimators.
Can we do better than those rates?

## Plenty of applications fit this setting:

Finance
Queueing systems
Inventory, distribution, logistic systems
Reliability models
MCMC in Bayesian statistics
Many many more...

## Example: An Asian Call Option (two-dim state)

Given observation times $t_{1}, t_{2}, \ldots, t_{\tau}, s_{0}>0$, and $X_{0}=0$, let

$$
\begin{aligned}
X\left(t_{j}\right) & =X\left(t_{j-1}\right)+\left(r-\sigma^{2} / 2\right)\left(t_{j}-t_{j-1}\right)+\sigma\left(t_{j}-t_{j-1}\right)^{1 / 2} Z_{j}, \\
S\left(t_{j}\right) & =s_{0} \exp \left[X\left(t_{j}\right)\right], \quad \text { (geometric Brownian motion) }
\end{aligned}
$$

where $U_{j} \sim U[0,1)$ and $Z_{j}=\Phi^{-1}\left(U_{j}\right) \sim N(0,1)$.
Running average: $\bar{S}_{j}=\frac{1}{j} \sum_{i=1}^{j} S\left(t_{i}\right)$.
Payoff at step $j=\tau$ is $Y=g_{\tau}\left(X_{\tau}\right)=\max \left[0, \bar{S}_{\tau}-K\right]$.
MC State: $\quad X_{j}=\left(S\left(t_{j}\right), \bar{S}_{j}\right)$.
Transition:

$$
X_{j}=\left(S\left(t_{j}\right), \bar{S}_{j}\right)=\varphi_{j}\left(S\left(t_{j-1}\right), \bar{S}_{j-1}, U_{j}\right)=\left(S\left(t_{j}\right), \frac{(j-1) \bar{S}_{j-1}+S\left(t_{j}\right)}{j}\right)
$$

Want to estimate $\mathbb{E}[Y]$, or distribution of $Y$, etc.

Take $\tau=12, T=1$ (one year), $t_{j}=j / \tau$ for $j=0, \ldots, \tau, K=100$, $s_{0}=100, r=0.05, \sigma=0.5$.
We make $n=10^{6}$ independent runs. Mean: 13.1. Max $=390.8$ In $53.47 \%$ of cases, the payoff is 0 .

Take $\tau=12, T=1$ (one year), $t_{j}=j / \tau$ for $j=0, \ldots, \tau, K=100$, $s_{0}=100, r=0.05, \sigma=0.5$.
We make $n=10^{6}$ independent runs. Mean: 13.1. Max $=390.8$ In $53.47 \%$ of cases, the payoff is 0 . Histogram of positive values:

Frequency $\left(\times 10^{3}\right)$

Confidence interval on $\mathbb{E}[Y]$ converges as $\mathcal{O}\left(n^{-1 / 2}\right)$. Can we do better?

Another histogram, with $n=4096$ runs.

Frequency

For histogram: MISE $=\mathcal{O}\left(n^{-2 / 3}\right)$.
For polygonal interpolation: MISE $=\mathcal{O}\left(n^{-4 / 5}\right)$. Same with KDE.
Can we do better?

## Randomized quasi-Monte Carlo (RQMC)

To estimate $\mu=\int_{(0,1)^{\mathrm{s}}} f(\mathbf{u}) d \mathbf{u}$, RQMC Estimator:

$$
\hat{\mu}_{n, \mathrm{rqmc}}=\frac{1}{n} \sum_{i=0}^{n-1} f\left(\mathbf{U}_{i}\right)
$$

with $P_{n}=\left\{\mathbf{U}_{0}, \ldots, \mathbf{U}_{n-1}\right\} \subset(0,1)^{s}$ an RQMC point set:
(i) each point $\mathbf{U}_{i}$ has the uniform distribution over $(0,1)^{s}$;
(ii) $P_{n}$ as a whole is a low-discrepancy point set.

$$
\begin{aligned}
\mathbb{E}\left[\hat{\mu}_{n, \text { rqmc }}\right] & =\mu \quad(\text { unbiased }), \\
\operatorname{Var}\left[\hat{\mu}_{n, \text { rqmc }}\right] & =\frac{\operatorname{Var}\left[f\left(\mathbf{U}_{i}\right)\right]}{n}+\frac{2}{n^{2}} \sum_{i<j} \operatorname{Cov}\left[f\left(\mathbf{U}_{i}\right), f\left(\mathbf{U}_{j}\right)\right] .
\end{aligned}
$$

We want to make the last sum as negative as possible.

## Randomized quasi-Monte Carlo (RQMC)

To estimate $\mu=\int_{(0,1)^{\text {s }}} f(\mathbf{u}) d \mathbf{u}$, RQMC Estimator:

$$
\hat{\mu}_{n, \mathrm{rqmc}}=\frac{1}{n} \sum_{i=0}^{n-1} f\left(\mathbf{U}_{i}\right)
$$

with $P_{n}=\left\{\mathbf{U}_{0}, \ldots, \mathbf{U}_{n-1}\right\} \subset(0,1)^{s}$ an RQMC point set:
(i) each point $\mathbf{U}_{i}$ has the uniform distribution over $(0,1)^{s}$;
(ii) $P_{n}$ as a whole is a low-discrepancy point set.

$$
\begin{aligned}
\mathbb{E}\left[\hat{\mu}_{n, \text { rqmc }}\right] & =\mu \quad(\text { unbiased }), \\
\operatorname{Var}\left[\hat{\mu}_{n, \text { rqmc }}\right] & =\frac{\operatorname{Var}\left[f\left(\mathbf{U}_{i}\right)\right]}{n}+\frac{2}{n^{2}} \sum_{i<j} \operatorname{Cov}\left[f\left(\mathbf{U}_{i}\right), f\left(\mathbf{U}_{j}\right)\right] .
\end{aligned}
$$

We want to make the last sum as negative as possible. Weak attempts: antithetic variates ( $n=2$ ), Latin hypercube sampling, $\ldots$

## Variance estimation:

Can compute $m$ independent realizations $X_{1}, \ldots, X_{m}$ of $\hat{\mu}_{n, \text { rqmc }}$, then estimate $\mu$ and $\operatorname{Var}\left[\hat{\mu}_{n, \text { rqmc }}\right]$ by their sample mean $\bar{X}_{m}$ and sample variance $S_{m}^{2}$. Could be used to compute a confidence interval.

Temptation: assume that $\bar{X}_{m}$ has the normal distribution. Beware: usually wrong unless $m \rightarrow \infty$.

## Stratification of the unit hypercube

Partition axis $j$ in $k_{j} \geq 1$ equal parts, for $j=1, \ldots$, s.
Draw $n=k_{1} \cdots k_{s}$ random points, one per box, independently.
Example, $s=2, k_{1}=12, k_{2}=8, n=12 \times 8=96$.

Stratified estimator:

$$
X_{\mathrm{s}, n}=\frac{1}{n} \sum_{j=0}^{n-1} f\left(\mathbf{U}_{j}\right)
$$

The crude MC variance with $n$ points can be decomposed as

$$
\operatorname{Var}\left[\bar{X}_{n}\right]=\operatorname{Var}\left[X_{\mathrm{s}, n}\right]+\frac{1}{n} \sum_{j=0}^{n-1}\left(\mu_{j}-\mu\right)^{2}
$$

where $\mu_{j}$ is the mean over box $j$.
The more the $\mu_{j}$ differ, the more the variance is reduced.

Stratified estimator:

$$
X_{\mathrm{s}, n}=\frac{1}{n} \sum_{j=0}^{n-1} f\left(\mathbf{U}_{j}\right)
$$

The crude MC variance with $n$ points can be decomposed as

$$
\operatorname{Var}\left[\bar{X}_{n}\right]=\operatorname{Var}\left[X_{\mathrm{s}, n}\right]+\frac{1}{n} \sum_{j=0}^{n-1}\left(\mu_{j}-\mu\right)^{2}
$$

where $\mu_{j}$ is the mean over box $j$.
The more the $\mu_{j}$ differ, the more the variance is reduced. If $f^{\prime}$ is continuous and bounded, and all $k_{j}$ are equal, then

$$
\operatorname{Var}\left[X_{s, n}\right]=\mathcal{O}\left(n^{-1-2 / s}\right)
$$

Stratified estimator:

$$
X_{\mathrm{s}, n}=\frac{1}{n} \sum_{j=0}^{n-1} f\left(\mathbf{U}_{j}\right)
$$

The crude MC variance with $n$ points can be decomposed as

$$
\operatorname{Var}\left[\bar{X}_{n}\right]=\operatorname{Var}\left[X_{\mathrm{s}, n}\right]+\frac{1}{n} \sum_{j=0}^{n-1}\left(\mu_{j}-\mu\right)^{2}
$$

where $\mu_{j}$ is the mean over box $j$.
The more the $\mu_{j}$ differ, the more the variance is reduced. If $f^{\prime}$ is continuous and bounded, and all $k_{j}$ are equal, then

$$
\operatorname{Var}\left[X_{\mathrm{s}, n}\right]=\mathcal{O}\left(n^{-1-2 / s}\right)
$$

For large $s$, not practical. For small $s$, not really better than midpoint rule with a grid when $f$ is smooth. But can still be applied to a few important random variables. Gives an unbiased estimator, and variance can be estimated by replicating $m \geq 2$ times.

## Randomly-Shifted Lattice

Example: lattice with $s=2, n=101, \mathbf{v}_{1}=(1,12) / 101$

## Randomly-Shifted Lattice

Example: lattice with $s=2, n=101, \mathbf{v}_{1}=(1,12) / 101$

## Randomly-Shifted Lattice

Example: lattice with $s=2, n=101, \mathbf{v}_{1}=(1,12) / 101$

## Randomly-Shifted Lattice

Example: lattice with $s=2, n=101, \mathbf{v}_{1}=(1,12) / 101$

Example of a digital net in base 2: Hammersley point set, $n=2^{8}=256, s=2$.

Example of a digital net in base 2: Hammersley point set, $n=2^{8}=256, s=2$.
$u_{i, 1}$

Example of a digital net in base 2 : Hammersley point set, $n=2^{8}=256, s=2$.

Example of a digital net in base 2: Hammersley point set, $n=2^{8}=256, s=2$.
$u_{i, 1}$

Example of a digital net in base 2: Hammersley point set, $n=2^{8}=256, s=2$.

## Random digital shift for digital net

Equidistribution in digital boxes is lost with random shift modulo 1, but can be kept with a random digital shift in base $b$.

In base 2: Generate $\mathbf{U} \sim U(0,1)^{s}$ and XOR it bitwise with each $\mathbf{u}_{i}$.
Example for $s=2$ :

$$
\begin{array}{rll}
\mathbf{u}_{i} & =(0.01100100 \ldots, & 0.10011000 \ldots)_{2} \\
\mathbf{U} & =(0.01001010 \ldots, & 0.11101001 \ldots)_{2} \\
\mathbf{u}_{i} \oplus \mathbf{U} & =(0.00101110 \ldots, & 0.01110001 \ldots)_{2}
\end{array}
$$

Each point has $U(0,1)$ distribution.
Preservation of the equidistribution $\left(k_{1}=3, k_{2}=5\right)$ :

$$
\begin{array}{rll}
\mathbf{u}_{i} & =\left(\begin{array}{ll}
0 . * * *, & 0 . * * * * *) \\
\mathbf{U} & =(0.010,
\end{array} 0.11101\right)_{2} \\
\mathbf{u}_{i} \oplus \mathbf{U} & =\left(\begin{array}{ll}
0 . * * *, & 0 . * * * * *)
\end{array}\right.
\end{array}
$$

$$
\begin{aligned}
\mathbf{U} & =(0.1270111220,0.3185275653)_{10} \\
& =(0.00100000100000111100,0.01010001100010110000)_{2}
\end{aligned}
$$

Changes the bits $3,9,15,16,17,18$ of $u_{i, 1}$ and the bits $2,4,8,9,13,15,16$ of $u_{i, 2}$.

Red and green squares are permuted $\left(k_{1}=k_{2}=4\right.$, first 4 bits of $\left.\mathbf{U}\right)$.

Cauchy-Shwartz inequalities of the form

$$
\operatorname{Var}\left[\hat{\mu}_{n, \mathrm{rqmc}}\right] \leq V^{2}(f) \cdot D^{2}\left(P_{n}\right)
$$

for all $f$ in some Hilbert space or Banach space $\mathcal{H}$, where
$V(f)=\|f-\mu\|_{\mathcal{H}}$ is the variation of $f$, and $D\left(P_{n}\right)$ is the discrepancy of $P_{n}$ (defined by an expectation in the RQMC case).

## Cauchy-Shwartz inequalities of the form

$$
\operatorname{Var}\left[\hat{\mu}_{n, \mathrm{rqmc}}\right] \leq V^{2}(f) \cdot D^{2}\left(P_{n}\right)
$$

for all $f$ in some Hilbert space or Banach space $\mathcal{H}$, where $V(f)=\|f-\mu\|_{\mathcal{H}}$ is the variation of $f$, and $D\left(P_{n}\right)$ is the discrepancy of $P_{n}$ (defined by an expectation in the RQMC case).

Lattice rules: For certain Hilbert spaces of smooth periodic functions $f$ with square-integrable partial derivatives of order up to $\alpha$ :

$$
D\left(P_{n}\right)=O\left(n^{-\alpha+\epsilon}\right) \text { for arbitrary small } \epsilon \text {. }
$$

Digital nets: "Classical" Koksma-Hlawka inequality for QMC: $f$ must have finite variation in the sense of Hardy and Krause (implies no discontinuity not aligned with the axes). Popular constructions achieve

$$
D\left(P_{n}\right)=O\left(n^{-1}(\ln n)^{s}\right)=O\left(n^{-1+\epsilon}\right) \text { for arbitrary small } \epsilon .
$$

More recent constructions offer better rates for smooth functions.

## Cauchy-Shwartz inequalities of the form

$$
\operatorname{Var}\left[\hat{\mu}_{n, \mathrm{rqmc}}\right] \leq V^{2}(f) \cdot D^{2}\left(P_{n}\right)
$$

for all $f$ in some Hilbert space or Banach space $\mathcal{H}$, where $V(f)=\|f-\mu\|_{\mathcal{H}}$ is the variation of $f$, and $D\left(P_{n}\right)$ is the discrepancy of $P_{n}$ (defined by an expectation in the RQMC case).

Lattice rules: For certain Hilbert spaces of smooth periodic functions $f$ with square-integrable partial derivatives of order up to $\alpha$ :

$$
D\left(P_{n}\right)=O\left(n^{-\alpha+\epsilon}\right) \text { for arbitrary small } \epsilon \text {. }
$$

Digital nets: "Classical" Koksma-Hlawka inequality for QMC: $f$ must have finite variation in the sense of Hardy and Krause (implies no discontinuity not aligned with the axes). Popular constructions achieve

$$
D\left(P_{n}\right)=O\left(n^{-1}(\ln n)^{s}\right)=O\left(n^{-1+\epsilon}\right) \text { for arbitrary small } \epsilon .
$$

More recent constructions offer better rates for smooth functions.
Bounds are conservative and too hard to compute in practice. Hidden constant and variation often increase fast with $s$.

## Classical Randomized Quasi-Monte Carlo (RQMC) for Markov Chains

One RQMC point for each sample path.
Put $\mathbf{V}_{i}=\left(\mathbf{U}_{i, 1}, \ldots, \mathbf{U}_{i, \tau}\right) \in(0,1)^{s}=(0,1)^{d \tau}$. Estimate $\mu$ by

$$
\hat{\mu}_{\mathrm{rqmc}, n}=\frac{1}{n} \sum_{i=0}^{n-1} \sum_{j=1}^{\tau} g_{j}\left(X_{i, j}\right)
$$

where $P_{n}=\left\{\mathbf{V}_{0}, \ldots, \mathbf{V}_{n-1}\right\} \subset(0,1)^{s}$ is an RQMC point set: (a) each point $\mathbf{V}_{i}$ has the uniform distribution over $(0,1)^{s}$;
(b) $P_{n}$ covers $(0,1)^{s}$ very evenly (i.e., has low discrepancy).

The dimension $s$ is often very large!

## Array-RQMC for Markov Chains

L., Lécot, Tuffin, et al. [2004, 2006, 2008, etc.]

## Earlier deterministic versions by Lécot et al.

Simulate an "array" of $n$ chains in "parallel."
At each step, use an RQMC point set $P_{n}$ to advance all the chains by one step. Seek global negative dependence across the chains.

Goal: Want small discrepancy (or "distance") between empirical distribution of $S_{n, j}=\left\{X_{0, j}, \ldots, X_{n-1, j}\right\}$ and theoretical distribution of $X_{j}$. If we succeed, these (unbiased) estimators will have small variance:

$$
\begin{aligned}
\mu_{j} & =\mathbb{E}\left[g_{j}\left(X_{j}\right)\right] \approx \hat{\mu}_{\text {arqma }, j, n}=\frac{1}{n} \sum_{i=0}^{n-1} g_{j}\left(X_{i, j}\right) \\
\operatorname{Var}\left[\hat{\mu}_{\text {arqmc }, j, n}\right] & =\frac{\operatorname{Var}\left[g_{j}\left(X_{i, j}\right)\right]}{n}+\frac{2}{n^{2}} \sum_{i=0}^{n-1} \sum_{k=i+1}^{n-1} \operatorname{Cov}\left[g_{j}\left(X_{i, j}\right), g_{j}\left(X_{k, j}\right)\right] .
\end{aligned}
$$

Some RQMC insight: To simplify the discussion, suppose $X_{j} \sim U(0,1)^{\ell}$.
This can be achieved (in principle) by a change of variable. We estimate

$$
\mu_{j}=\mathbb{E}\left[g_{j}\left(X_{j}\right)\right]=\mathbb{E}\left[g_{j}\left(\varphi_{j}\left(X_{j-1}, \mathbf{U}\right)\right)\right]=\int_{[0,1)^{\ell+d}} g_{j}\left(\varphi_{j}(\mathbf{x}, \mathbf{u})\right) d \mathbf{x} d \mathbf{u}
$$

(we take a single $j$ here) by

$$
\hat{\mu}_{\text {arqma }, j, n}=\frac{1}{n} \sum_{i=0}^{n-1} g_{j}\left(X_{i, j}\right)=\frac{1}{n} \sum_{i=0}^{n-1} g_{j}\left(\varphi_{j}\left(X_{i, j-1}, \mathbf{U}_{i, j}\right)\right) .
$$

This is (roughly) RQMC with the point set $Q_{n}=\left\{\left(X_{i, j-1}, \mathbf{U}_{i, j}\right), 0 \leq i<n\right\}$. We want $Q_{n}$ to have low discrepancy (LD) (be highly uniform) over $[0,1)^{\ell+d}$.

This can be achieved (in principle) by a change of variable. We estimate

$$
\mu_{j}=\mathbb{E}\left[g_{j}\left(X_{j}\right)\right]=\mathbb{E}\left[g_{j}\left(\varphi_{j}\left(X_{j-1}, \mathbf{U}\right)\right)\right]=\int_{[0,1)^{\ell+d}} g_{j}\left(\varphi_{j}(\mathbf{x}, \mathbf{u})\right) d \mathbf{x} d \mathbf{u}
$$

(we take a single $j$ here) by

$$
\hat{\mu}_{\text {arqmc }, j, n}=\frac{1}{n} \sum_{i=0}^{n-1} g_{j}\left(X_{i, j}\right)=\frac{1}{n} \sum_{i=0}^{n-1} g_{j}\left(\varphi_{j}\left(X_{i, j-1}, \mathbf{U}_{i, j}\right)\right) .
$$

This is (roughly) RQMC with the point set $Q_{n}=\left\{\left(X_{i, j-1}, \mathbf{U}_{i, j}\right), 0 \leq i<n\right\}$. We want $Q_{n}$ to have low discrepancy (LD) (be highly uniform) over $[0,1)^{\ell+d}$. We do not choose the $X_{i, j-1}$ 's in $Q_{n}$ : they come from the simulation. To construct the (randomized) $\mathbf{U}_{i, j}$, select a LD point set

$$
\tilde{Q}_{n}=\left\{\left(\mathbf{w}_{0}, \mathbf{U}_{0, j}\right), \ldots,\left(\mathbf{w}_{n-1}, \mathbf{U}_{n-1, j}\right)\right\},
$$

where the $\mathbf{w}_{i} \in[0,1)^{\ell}$ are fixed and each $\mathbf{U}_{i, j} \sim U(0,1)^{d}$.
Permute the states $X_{i, j-1}$ so that $X_{\pi_{j}(i), j-1}$ is "close" to $\mathbf{w}_{i}$ for each $i$ (LD between the two sets), and compute $X_{i, j}=\varphi_{j}\left(X_{\pi_{j}(i), j-1}, \mathbf{U}_{i, j}\right)$ for each $i$.
Example: If $\ell=1$, can take $\mathbf{w}_{i}=(i+0.5) / n$ and just sort the states. For $\ell>1$, there are various ways to define the matching (multivariate sort).

## Array-RQMC algorithm

$X_{i, 0} \leftarrow x_{0}\left(\right.$ or $\left.X_{i, 0} \leftarrow x_{i, 0}\right)$ for $i=0, \ldots, n-1$;
for $j=1,2, \ldots, \tau$ do
Compute the permutation $\pi_{j}$ of the states (for matching); Randomize afresh $\left\{\mathbf{U}_{0, j}, \ldots, \mathbf{U}_{n-1, j}\right\}$ in $\tilde{Q}_{n}$;

$$
X_{i, j}=\varphi_{j}\left(X_{\pi_{j}(i), j-1}, \mathbf{U}_{i, j}\right), \text { for } i=0, \ldots, n-1
$$

$$
\hat{\mu}_{\text {arqmc }, j, n}=\bar{Y}_{n, j}=\frac{1}{n} \sum_{i=0}^{n-1} g\left(X_{i, j}\right) ;
$$

end for
Estimate $\mu$ by the average $\bar{Y}_{n}=\hat{\mu}_{\text {arqmc }, n}=\sum_{j=1}^{\tau} \hat{\mu}_{\text {arqmc }, j, n}$.

## Array-RQMC algorithm

$X_{i, 0} \leftarrow x_{0}\left(\right.$ or $\left.X_{i, 0} \leftarrow x_{i, 0}\right)$ for $i=0, \ldots, n-1$;
for $j=1,2, \ldots, \tau$ do
Compute the permutation $\pi_{j}$ of the states (for matching); Randomize afresh $\left\{\mathbf{U}_{0, j}, \ldots, \mathbf{U}_{n-1, j}\right\}$ in $\tilde{Q}_{n}$;

$$
X_{i, j}=\varphi_{j}\left(X_{\pi_{j}(i), j-1}, \mathbf{U}_{i, j}\right), \text { for } i=0, \ldots, n-1
$$

$$
\hat{\mu}_{\text {arqmc }, j, n}=\bar{Y}_{n, j}=\frac{1}{n} \sum_{i=0}^{n-1} g\left(X_{i, j}\right) ;
$$

end for
Estimate $\mu$ by the average $\bar{Y}_{n}=\hat{\mu}_{\text {arqme }, n}=\sum_{j=1}^{\tau} \hat{\mu}_{\text {arqmc }, j, n}$.

Proposition: (i) The average $\bar{Y}_{n}$ is an unbiased estimator of $\mu$.
(ii) The empirical variance of $m$ independent realizations gives an unbiased estimator of $\operatorname{Var}\left[\bar{Y}_{n}\right]$.

## Key issues:

1. How can we preserve LD of $S_{n, j}=\left\{X_{0, j}, \ldots, X_{n-1, j}\right\}$ as $j$ increases?
2. Can we prove that $\operatorname{Var}\left[\hat{\mu}_{\text {arqma }, j, n}\right]=\mathcal{O}\left(n^{-\alpha}\right)$ for some $\alpha>1$ ?

How? What $\alpha$ ?
3. How does it behave empirically for moderate $n$ ?

Intuition: Write discrepancy measure of $S_{n, j}$ as the mean square integration error (or variance) when integrating some function $\psi:[0,1)^{\ell+d} \rightarrow \mathbb{R}$ using $Q_{n}$.
Use RQMC theory to show it is small if $Q_{n}$ has LD. Then use induction.

## Convergence results and applications

L., Lécot, and Tuffin [2006, 2008]: Special cases: convergence at MC rate, one-dimensional, stratification, etc. Var in $\mathcal{O}\left(n^{-3 / 2}\right)$.

Gerber and Chopin [2015]: Sequential QMC.

## Mapping chains to points when $\ell>2$

1. Multivariate batch sort:

Sort the states (chains) by first coordinate, in $n_{1}$ packets of size $n / n_{1}$. Sort each packet by second coordinate, in $n_{2}$ packets of size $n / n_{1} n_{2}$.

At the last level, sort each packet of size $n_{\ell}$ by the last coordinate. Choice of $n_{1}, n_{2}, \ldots, n_{\ell}$ ?

States of the chains
Sobol' net + digital shift

## Lowering the state dimension

For $\ell>1$ : Define a transformation $h: \mathcal{X} \rightarrow[0,1)^{c}$ for $c<\ell$. Sort the transformed points $h\left(X_{i, j}\right)$ in $c$ dimensions.
Now we only need $c+d$ dimensions for the RQMC point sets; $c$ for the mapping and $d$ to advance the chain.
Choice of $h$ : states mapped to nearby values should be nearly equivalent.

For $c=1, \mathcal{X}$ is mapped to $[0,1)$, which leads to a one-dim sort.
The mapping $h$ with $c=1$ can be based on a space-filling curve:
Wächter and Keller [2008] use a Lebesgue Z-curve and mention others; Gerber and Chopin [2015] use a Hilbert curve and prove o $\left(n^{-1}\right)$ convergence for the variance when used with digital nets and Owen nested scrambling. A Peano curve would also work in base 3.

Reality check: We only need a good pairing between states and RQMC points. Any good way of doing this is welcome!

## Sorting by a Hilbert curve

Suppose the state space is $\mathcal{X}=[0,1)^{\ell}$.
Partition this cube into $2^{m \ell}$ subcubes of equal size.
When a subcube contains more than one point (a collision), we could split it again in $2^{\ell}$. But in practice, we rather fix $m$ and neglect collisions.

The Hilbert curve defines a way to enumerate (order) the subcubes so that successive subcubes are always adjacent. This gives a way to sort the points. Colliding points are ordered arbitrarily. We precompute and store the map from point coordinates (first $m$ bits) to its position in the list.

Then we can map states to points as if the state had one dimension. We use RQMC points in $1+d$ dimensions, ordered by first coordinate, which is used to match the states, and $d$ (randomized) coordinates are used to advance the chains.

## Hilbert curve sort

Map the state to $[0,1]$, then sort.

States of the chains

## Hilbert curve sort

Map the state to $[0,1]$, then sort.

## States of the chains

## Hilbert curve sort

Map the state to $[0,1]$, then sort.

States of the chains

## Hilbert curve sort

Map the state to $[0,1]$, then sort.

States of the chains

## What if state space is not $[0,1)^{\ell}$ ?

Ex.: For the Asian option, $\mathcal{X}=[0, \infty)^{2}$.
Then one must define a transformation $\psi: \mathcal{X} \rightarrow[0,1)^{\ell}$ so that the transformed state is approximately uniformly distributed over $[0,1)^{\ell}$.

Not easy to find a good $\psi$ in general!
Gerber and Chopin [2015] propose using a logistic transformation for each coordinate, combined with trial and error.

A lousy choice could possibly damage efficiency.

## Hilbert curve batch sort

Perform a multivariate batch sort, or a split sort, and then enumerate the boxes as in the Hilbert curve sort.
Advantage: the state space can be $\mathbb{R}^{\ell}$.

## Convergence results and proofs

For $\ell=1, \mathcal{O}\left(n^{-3 / 2}\right)$ variance has been proved under some conditions.
For $\ell>1$, worst-case error of $\mathcal{O}\left(n^{-1 /(\ell+1)}\right)$ has been proved in deterministic settings under strong conditions on $\varphi_{j}$, using a batch sort (El Haddad, Lécot, L'Ecuyer 2008, 2010).

Gerber and Chopin (2015) proved $o\left(n^{-1}\right)$ variance, for Hilbert sort and digital net with nested scrambling.

## Proved convergence results

L., Lécot, Tuffin [2008] + some extensions.

Simple case: suppose $\ell=d=1, \mathcal{X}=[0,1]$, and $X_{j} \sim U(0,1)$. Define

$$
\begin{aligned}
\Delta_{j} & =\sup _{x \in \mathcal{X}}\left|\hat{F}_{j}(x)-F_{j}(x)\right| \quad \text { (star discrepancy of states) } \\
V_{\infty}\left(g_{j}\right) & \left.=\int_{0}^{1}\left|\frac{d g_{j}(x)}{d x}\right| d x \quad \text { (corresponding variation of } g_{j}\right) \\
D_{j}^{2} & =\int_{0}^{1}\left(\hat{F}_{j}(x)-F_{j}(x)\right)^{2} d x=\frac{1}{12 n^{2}}+\frac{1}{n} \sum_{i=0}^{n-1}\left((i+0.5 / n)-F_{j}\left(X_{(i), j}\right)\right. \\
V_{2}^{2}\left(g_{j}\right) & \left.=\int_{0}^{1}\left|\frac{d g_{j}(x)}{d x}\right|^{2} d x \quad \text { (corresp. square variation of } g_{j}\right) .
\end{aligned}
$$

We have

$$
\begin{aligned}
\left|\bar{Y}_{n, j}-\mathbb{E}\left[g_{j}\left(X_{j}\right)\right]\right| & \leq \Delta_{j} V_{\infty}\left(g_{j}\right), \\
\operatorname{Var}\left[\bar{Y}_{n, j}\right]=\mathbb{E}\left[\left(\bar{Y}_{n, j}-\mathbb{E}\left[g_{j}\left(X_{j}\right)\right]\right)^{2}\right] & \leq \mathbb{E}\left[D_{j}^{2}\right] V_{2}^{2}\left(g_{j}\right) .
\end{aligned}
$$

## Convergence results and proofs, $\ell=1$

Assumption 1. $\varphi_{j}(x, u)$ non-decreasing in $u$. Also $n=k^{2}$ for some integer $k$ and that each square of the $k \times k$ grid contains exactly one RQMC point.

Let $\Lambda_{j}=\sup _{0 \leq z \leq 1} V\left(F_{j}(z \mid \cdot)\right)$.
Proposition. (Worst-case error.) Under Assumption 1,

$$
\Delta_{j} \leq n^{-1 / 2} \sum_{k=1}^{j}\left(\Lambda_{k}+1\right) \prod_{i=k+1}^{j} \Lambda_{i}
$$

Corollary. If $\Lambda_{j} \leq \rho<1$ for all $j$, then

$$
\Delta_{j} \leq \frac{1+\rho}{1-\rho} n^{-1 / 2}
$$

## Convergence results and proofs, $\ell=1$

Assumption 2. (Stratification) Assumption 1 holds, $\varphi_{j}$ also non-decreasing in $x$, and randomized parts of the points are uniformly distributed in the cubes and pairwise independent (or negatively dependent) conditional on the cubes in which they lie.
Proposition. (Variance bound.) Under Assumption 2,

$$
\mathbb{E}\left[D_{j}^{2}\right] \leq\left(\frac{1}{4} \sum_{\ell=1}^{j}\left(\Lambda_{\ell}+1\right) \prod_{i=\ell+1}^{j} \Lambda_{i}^{2}\right) n^{-3 / 2}
$$

Corollary. If $\Lambda_{j} \leq \rho<1$ for all $j$, then

$$
\begin{aligned}
\mathbb{E}\left[D_{j}^{2}\right] & \leq \frac{1+\rho}{4\left(1-\rho^{2}\right)} n^{-3 / 2}=\frac{1}{4(1-\rho)} n^{-3 / 2} \\
\operatorname{Var}\left[\bar{Y}_{n, j}\right] & \leq \frac{1}{4(1-\rho)} V_{2}^{2}\left(g_{j}\right) n^{-3 / 2}
\end{aligned}
$$

These bounds are uniform in $j$.

## Convergence results and proofs, $\ell>1$

Worst-case error of $\mathcal{O}\left(n^{-1 /(\ell+1)}\right)$ has been proved in a deterministic setting for a discrete state space in $\mathcal{X} \subseteq \mathbb{Z}^{\ell}$, and for a continuous state space $\mathcal{X} \subseteq \mathbb{R}^{\ell}$ under strong conditions on $\varphi_{j}$, using a batch sort (El Haddad, Lécot, L'Ecuyer 2008, 2010).

Gerber and Chopin (2015) proved $o\left(n^{-1}\right)$ for the variance, for Hilbert sort and digital net with nested scrambling.

## Example: Asian Call Option

$S(0)=100, K=100, r=0.05, \sigma=0.15, t_{j}=j / 52, j=0, \ldots, \tau=13$.
RQMC: Sobol' points with linear scrambling + random digital shift.
Similar results for randomly-shifted lattice + baker's transform. $\log _{2} \operatorname{Var}\left[\hat{\mu}_{\mathrm{RQMC}, n}\right]$

## Example: Asian Call Option

$S(0)=100, K=100, r=\ln (1.09), \sigma=0.2$,
$t_{j}=(230+j) / 365$, for $j=1, \ldots, \tau=10$.

|  | Korobov+baker | -2.01 | $3.3 \times 10^{6}$ | 567 |

VRF for $n=2^{20}$. CPU time for $m=100$ replications.

## A small example with a one-dimensional state

Let $\theta \in[0,1)$ and let $G_{\theta}$ be the cdf of $Y=\theta U+(1-\theta) V$, where $U, V$ are indep. $U(0,1)$. We define a Markov chain by

$$
\begin{aligned}
X_{0} & =U_{0} \sim U(0,1) \\
X_{j} & =\varphi_{j}\left(X_{j-1}, U_{j}\right)=G_{\theta}\left(\theta X_{j-1}+(1-\theta) U_{j}\right), \quad j \geq 1
\end{aligned}
$$

where $U_{j} \sim U(0,1)$. Then, $X_{j} \sim U(0,1)$ for all $j$.
We consider various functions $g_{j}: g_{j}(x)=x-1 / 2, g_{j}(x)=x^{2}-1 / 3$, $g_{j}(x)=\sin (2 \pi x), g_{j}(x)=e^{x}-e+1$ (all smooth), $g_{j}(x)=(x-1 / 2)^{+}-1 / 8$ (kink), $g_{j}(x)=\mathbb{I}[x \leq 1 / 3]-1 / 3$ (step).
They all have $\mathbb{E}\left[g_{j}\left(X_{j}\right)\right]=0$. We pretend we do not know this and want to see how well we can estimate these expectations by simulation.
We also want to see how well we can estimate the exact distribution of $X_{j}$ (uniform) by the empirical distribution of $X_{0, j}, \ldots, X_{n-1, j}$.

## One-dimensional example

We take $\rho=0.3$ and $j=5$.
For array-RQMC, we take $X_{i, 0}=w_{i}=(i-1 / 2) / n$.
We tried different array-RQMC variants, for $n=2^{9}$ to $n=2^{21}$.
We did $m=200$ independent replications for each $n$.
We fitted a linear regression of $\log _{2} \operatorname{Var}\left[\bar{Y}_{n, j}\right]$ vs $\log _{2} n$, for various $g_{j}$

## One-dimensional example

We take $\rho=0.3$ and $j=5$.

We tried different array-RQMC variants, for $n=2^{9}$ to $n=2^{21}$.
We did $m=200$ independent replications for each $n$.
We fitted a linear regression of $\log _{2} \operatorname{Var}\left[\bar{Y}_{n, j}\right]$ vs $\log _{2} n$, for various $g_{j}$
We also looked at uniformity measures of the set of $n$ states at step $j$. For example, the Kolmogorov-Smirnov (KS) and Cramer von Mises (CvM) test statistics, denoted $\mathrm{KS}_{\mathrm{j}}$ and $D_{j}$. With ordinary $\mathrm{MC}, \mathbb{E}\left[\mathrm{KS}_{\mathrm{j}}\right]$ and $\mathbb{E}\left[D_{j}\right]$ converge as $\mathcal{O}\left(n^{-1}\right)$ for any $j$.
For stratification, we have a proof that

$$
\mathbb{E}\left[D_{j}^{2}\right] \leq \frac{n^{-3 / 2}}{4(1-\rho)}=\frac{1-\theta}{4(1-2 \theta)} n^{-3 / 2}
$$

## Conclusion

We have convergence proofs for special cases, but not yet for the rates we observe in examples.

Many other sorting strategies remain to be explored.
Other examples and applications. Higher dimension.
Array-RQMC is good not only to estimate the mean more accurately, but also to estimate the entire distribution of the state.
