Abstract
This article extends neural networks to the case of an uncountable number of hidden units, in several ways. In the first approach proposed, a finite parametrization is possible, allowing gradient-based learning. While having the same number of parameters as an ordinary neural network, its internal structure suggests that it can represent some smooth functions much more compactly. Under mild assumptions, we also find better error bounds than with ordinary neural networks. Furthermore, this parametrization may help reducing the problem of saturation of the neurons. In a second approach, the input-to-hidden weights are fully non-parametric, yielding a kernel machine for which we demonstrate a simple kernel formula. Interestingly, the resulting kernel machine can be made hyperparameter-free and still generalizes in spite of an absence of explicit regularization.

1 Introduction
In (Neal, 1994) neural networks with an infinite number of hidden units were introduced, showing that they could be interpreted as Gaussian processes, and this work served as inspiration for a large body of work on Gaussian processes. Neal’s work showed a counter-example to two common beliefs in the machine learning community: (1) that a neural network with a very large number of hidden units would overfit and (2) that it would not be feasible to numerically optimize such huge networks. In spite of Neal’s work, these beliefs are still commonly held. In this paper we return to Neal’s idea and study a number of extensions of neural networks to the case where the number of hidden units is uncountable, showing that they yield implementable algorithms with interesting properties.

Consider a neural network with one hidden layer (and $h$ hidden neurons), one output neuron and a transfer function $g$. Let us denote $V$ the input-to-hidden weights, $a_i(i = 1, \ldots, h)$ the hidden-to-output weights and $\beta$ the output unit bias (the hidden units biases are included in $V$).

The output of the network with input $x$ is then

$$f(x) = \beta + \sum_i a_i g(\bar{x} \cdot V_i)$$

(1)
where $V_i$ is the $i$-th column of matrix $V$ and $\tilde{x}$ is the vector with 1 appended to $x$. The output of the $i$-th hidden neuron is $g(\tilde{x} \cdot V_i)$. For antisymmetric functions $g$ such as $\tanh$, we can without any restriction consider the case where all the $a_i$’s are nonnegative, since changing the sign of $a_i$ is equivalent to changing the sign of $V_i$.

In ordinary neural networks, we have an integer index $i$. To obtain an uncountable number of hidden units, we introduce a continuous-valued (possibly vector-valued) index $u \in \mathbb{R}^m$. We can replace the usual sum over hidden units by an integral that goes through the different weight vectors that can be assigned to a hidden unit:

$$f(x) = \beta + \int_{E \subset \mathbb{R}^m} a(u)g[\tilde{x} \cdot V(u)] \, du \quad (2)$$

where $a : E \rightarrow \mathbb{R}$ is the hidden-to-output weight function, and $V : E \rightarrow \mathbb{R}^{d+1}$ is the input-to-hidden weight function.

How can we prevent overfitting in these settings? In this paper we discuss three types of solutions: (1) finite-dimensional representations of $V$, (2) $L^1$ regularization of the output weights with $a$ and $V$ completely free, (3) $L^2$ regularization of the output weights, with $a$ and $V$ completely free.

Solutions of type 1 are completely new and give new insights on neural networks. Many possible parametrizations are possible to map the “hidden unit index” (a finite-dimensional vector) to a weight vector. This parametrization allows us to construct a representation theorem similar to Kolmogorov’s, i.e. we show that functions from $K$ compact of $\mathbb{R}^d$ to $\mathbb{R}$ can be represented by $d + 1$ functions from $[0, 1]$ to $\mathbb{R}$. Here we study an affine-by-part parametrization, with interesting properties. In particular, it is shown that approximation error can be bounded in $O(h^{-2})$ where $h$ is proportional to the number of free parameters, whereas ordinary neural networks enjoy a $O(h^{-1})$ error bound. Solutions of type 2 ($L^1$ regularization) were already presented in (Bengio et al., 2005) so we do not focus on them here. They yield a convex formulation but with an infinite number of variables, requiring approximate optimization when the number of inputs is not tiny. Solutions of type 3 ($L^2$ regularization) give rise to kernel machines that are similar to Gaussian processes, albeit with a type of kernel not commonly used in the literature. We show that an analytic formulation of the kernel is possible when hidden units compute the sign of a dot product (i.e., with formal neurons). Interestingly, experiments suggest that this kernel is more resistant to overfitting than the Gaussian kernel, allowing to train working models with no hyper-parameters whatsoever.

## 2 Affine neural networks

### 2.1 Core idea

We study here a special case of the solutions of type (1), with a finite-dimensional parametrization of the continuous neural network, based on parametrizing the term $V(u)$ in eq. 2, where $u$ is scalar.

$$f(x) = \beta + \int_{E \subset \mathbb{R}} a(u)g[\tilde{x} \cdot V(u)] \, du \quad (3)$$

where $V$ is a function from the compact set $E$ to $\mathbb{R}^{d+1}$ ($d$ being the dimension of $x$).

If $u$ is scalar, we can get rid of the function $a$ and include it in $V$. Indeed, let us consider a primitive $A$ of $a$. It is invertible because $a$ is nonnegative and one can consider only the $u$ such that $a(u) > 0$ (because the $u$ such that $a(u) = 0$ do not modify the value of the integral). Making the change of variable $t = A(u)$ (choosing any primitive $A$), we have $dt = a(u)du$. $V(u)$ will become $V(A^{-1}(t))$ which can be written
$V_A(t)$ with $V_A = V \circ A^{-1}$. An equivalent parametrization is therefore

$$f(x) = \beta + \alpha \int_{A^{-1}(E)} g[\tilde{x} \cdot V_A(t)] \, dt.$$  

This formulation shows that the only thing to optimize will be the function $V$, and the scalars $\alpha$ and $\beta$, getting rid of the optimization of the hidden-to-output weights. In the remainder of the paper, $V_A$ will simply be denoted $V$. If we want the domain of integration to be of length 1, we have to make another change of variable $z = \frac{t - t_0}{\alpha}$ where $\alpha$ is the length of $E$ and $t_0 = \inf(A^{-1}(E))$.

$$f(x) = \alpha \int_0^1 g[\tilde{x} \cdot V(z)] \, dz.$$  \hspace{1cm} (4)

Let us denote by $\phi$ the mapping defined by

$$\phi_{V,\alpha,\beta} = x \mapsto \beta + \alpha \int_0^1 g[\tilde{x} \cdot V(z)] \, dz$$

**Lemma 1.** When $V$ is a piecewise-constant function such that $V(z) = V_i$ when $p_{i-1} \leq z < p_i$ with $a_0 = 0$, $\alpha = \sum a_i$, and $p_i = \frac{1}{\alpha} \sum_{j=0}^i a_j$, we have an ordinary neural network:

$$\beta + \alpha \int_0^1 g[\tilde{x} \cdot V(z)] \, dz = \beta + \sum a_i g(\tilde{x} \cdot V_i)$$  \hspace{1cm} (5)

The proof is provided in the Appendix.

At this point, we can make an important comment. If $x \in \mathbb{R}^d$ we can rewrite $\tilde{x} \cdot V(z) = V^{d+1}(z) + \sum_{i=1}^d x_i V^i(z)$ where $V^i$ is a function from $[0, 1]$ to $\mathbb{R}$ and $x_i$ is the $i$-th coordinate of $x$. But $f$ is a function from $K$ compact of $\mathbb{R}^d$ to $\mathbb{R}$. Using the neural network function approximation theorem of (Hornik, Stinchcombe and White, 1989), the following theorem therefore follows:

**Theorem 1.** Any Borel measurable function $f$ from $K$ compact of $\mathbb{R}^d$ to $\mathbb{R}$ can, with an arbitrary precision, be defined by $d + 1$ functions $V^i$ from $[0, 1]$ to $\mathbb{R}$ and two reals $\alpha$ and $\beta$ with the relation

$$f(x) = \beta + \alpha \int_0^1 \tanh \left( \sum_{i=1}^d V^i(z) \cdot x_i + V^{n+1}(z) \right) \, dz$$

The proof is provided in the Appendix.

This result is reminiscent of Kolmogorov’s superposition theorem (Kolmogorov, 1957), but here we show that the functions $V^i$ can be directly optimized in order to obtain a good function approximation.

### 2.2 Approximating an Integral

In this work we consider a parametrization of $V$ involving a finite number of parameters, and we optimize over these parameters. Since $f$ is linked to $V$ by an integral, it suggests to look at parametrizations yielding good approximation of an integral. Several such parametrizations already exist:

- piecewise constant functions, used in the rectangle method. This is the simplest approximation, corresponding to ordinary neural networks (eq. 1),
• piecewise affine functions, used in the trapezoid method. This approximation yields better results and will be the one studied here, which we coin “Affine Neural Network”.

• polynomials, used in Simpson’s method, which allow even faster convergence. However, we were not able to compute the integral of polynomials through the function tanh.

2.3 Piecewise Affine Parametrization

Using a piecewise affine parametrization, we consider \( V \) of the form:

\[
V(z) = V_{i-1} + \frac{z - p_{i-1}}{p_i - p_{i-1}} (V_i - V_{i-1}) \quad \text{when} \quad p_{i-1} \leq z < p_i,
\]

that is to say \( V \) is linear between \( p_{i-1} \) and \( p_i \), \( V(p_{i-1}) = V_{i-1} \) and \( V(p_i) = V_i \) for each \( i \). This will ensure the continuity of \( V \).

In addition, we will set \( V_{n+1} = V_1 \) to avoid border effects and obtain an extra segment for the same number of parameters.

Rewriting \( p_i - p_{i-1} = a_i \) and \( V(z) = V_i(z) \) for \( p_{i-1} \leq z < p_i \), the output \( f(x) \) for an input example \( x \) can be written:

\[
f(x) = \sum_i \int_{z=p_{i-1}}^{p_i} \tanh \left[ V_i(z) \cdot \hat{x} \right] \, dz
= \sum_i \frac{a_i}{(V_i - V_{i-1}) \cdot \hat{x}} \ln \left( \frac{\cosh(V_i \cdot \hat{x})}{\cosh(V_{i-1} \cdot \hat{x})} \right)
\]

In the case where \( V_i \cdot \hat{x} = V_{i-1} \cdot \hat{x} \), the affine piece is indeed constant and the term in the sum becomes \( a_i \tanh(V_i \cdot \hat{x}) \), as in a usual neural network. To respect the continuity of function \( V \), we should restrict the \( a_i \) to be positive, since \( p_i \) must be greater than \( p_{i-1} \).

2.3.1 Is the continuity of \( V \) necessary?

As said before, we want to enforce the continuity of \( V \). The first reason is that the trapezoid method uses continuous functions and the results concerning that method can therefore be used for the affine approximation. Besides, using a continuous \( V \) allows us to have the same number of parameters for the same number of hidden units. Indeed, using a piecewise affine discontinuous \( V \) would require twice as many parameters for the input weights for the same number of hidden units.

The reader might notice at that point that there is no bijection between \( V \) and \( f \). Indeed, since \( V \) is only defined by its integral, we can switch two different pieces of \( V \) without modifying \( f \).

2.4 Extension to multiple output neurons

The formula of the output is a linear combination of the \( a_i \), as in the ordinary neural network. Thus, the extension to \( l \) output neurons is straightforward using the formula

\[
f_j(x) = \sum_i \frac{a_{ij}}{(V_i - V_{i-1}) \cdot \hat{x}} \ln \left( \frac{\cosh(V_i \cdot \hat{x})}{\cosh(V_{i-1} \cdot \hat{x})} \right)
\]

for \( j = 1, \ldots, l \).
2.5 Piecewise affine versus piecewise constant

Consider a target function \( f^* \) that we would like to approximate, and a target \( V^* \) that gives rise to it. Before going any further, we should ask two questions:

- is there a relation between the quality of the approximation of \( f^* \) and the quality of approximation of \( V^* \)?
- are piecewise affine functions (i.e. the affine neural networks) more appropriate to approximate an arbitrary function than the piecewise constant ones (i.e. ordinary neural networks)?

We remind the reader that the function \( f \) is defined by

\[
\phi_{V, \alpha, \beta} = x \mapsto \beta + \alpha \int_0^1 g[\tilde{x} \cdot V(z)] \, dz.
\]

**Theorem 2.** \( \forall x, \forall V^*, \forall \alpha^*, \forall \beta^*, \forall V \), we have

\[
|\phi_{V, \alpha^*, \beta^*}(x) - \phi_{V^*, \alpha^*, \beta^*}(x)| \leq 2\alpha^* \int_{z=0}^1 \tanh ((V(z) - V^*(z)) \cdot \tilde{x}) \, dz
\]

The proof is provided in the Appendix.

Thus, if \( V \) is never far from \( V^* \) and \( x \) is in a compact set \( K \), we are sure that the approximated function will be close to the true function. This justifies the attempts to better approximate \( V^* \).

We can then make an obvious remark: if we restrict the model to a finite number of hidden neurons, it will never be possible to have a piecewise constant function equal to a piecewise affine function (apart from the trivial case where all affine functions are in fact constant). On the other hand, any piecewise constant function composed of \( h \) pieces can be represented by a continuous piecewise affine function composed of at most \( 2h \) pieces (half of the pieces being constant and the other half being used to avoid discontinuities), given that we allow vertical pieces (which is true in the affine framework).

Are affine neural networks providing a better parametrization than the ordinary neural networks? The following theorem suggests it:

**Theorem 3.** Let \( f^* = \phi_{V^*, \alpha^*, \beta^*} \) with \( V^* \) a function with a finite number of discontinuities and \( C^1 \) on each interval between two discontinuities. Then there exists a scalar \( C \), a piecewise affine continuous function \( V \) with \( h \) pieces and two scalars \( \alpha \) and \( \beta \) such that, for all \( x \), \( |\phi_{V, \alpha, \beta}(x) - f^*(x)| \leq Ch^{-2} \) (pointwise convergence).

The proof is provided in the Appendix. In comparison, we can only guarantee a bound in \( O(h^{-1}) \) for ordinary neural networks.

An interesting question would be to characterize the set of such functions \( f^* \). It seems that the answer is far from trivial.

Besides, one must note that these are upper bounds. It therefore does not guarantee that the optimization of affine neural networks will always be better than the one of ordinary neural networks. Furthermore, one shall keep in mind that both methods are subject to local minima of the training criterion. However, we will see in the following section that the affine neural networks appear less likely to get stuck during the optimization than ordinary neural networks.

2.6 Implied prior distribution

Up to now we have only considered a parametrized class of functions. We know that gradient descent or ordinary \( C^2 \) regularization are more likely to yield small values of the parameters, the latter directly corresponding to a zero-mean Gaussian prior over the parameters. Hence to visualize and better understand
this new parametrization, we define a zero-mean Gaussian prior distribution on the parameters $\beta$, $a_i$ and $V_i$ ($1 \leq i \leq h$), and sample from the corresponding functions.

We sampled from each of the two neural networks (ordinary discrete net and continuous affine net) with one input neuron, different numbers of hidden units ($n_h$ pieces) and zero-mean Gaussian priors with variance $\sigma_u$ for input-to-hidden weights, variance $\sigma_a$ for the input biases, variance $\sigma_b$ for the output bias and variance $\frac{\sigma_w}{\sqrt{h}}$ for hidden-to-output weights (scaled in terms of the number of hidden units $h$, to keep constant the variance of the network output as $h$ changes). Randomly obtained samples are shown in figure 1. The $x$ axis represents the value of the input of the network and the $y$ axis is the associated output of the network.

![Figure 1: Functions generated by an ordinary neural network (top) and an affine neural network (bottom) with $\sigma_u = 5, n_h = 2$ (first column), $\sigma_u = 20, n_h = 2$ (second column), $\sigma_u = 100, n_h = 2$ (third column), $\sigma_u = 5, n_h = 10000$ (fourth column) and $\sigma_u = 100, n_h = 10000$ (fifth column). We always have $\sigma_a = \sigma_u$ and $\sigma_b = w$.](image)

The different priors over the functions show a very specific trend: when $\sigma_u$ grows, the ordinary (tanh) neural network tends to saturate whereas the affine neural network does so much less often. This can easily be explained by the fact that, if $|V_i \cdot \hat{x}|$ and $|V_{i+1} \cdot \hat{x}|$ are both much greater than 1, hidden unit $i$ stays in the saturation zone when $V$ is piecewise constant (ordinary neural network). However, with a piecewise affine $V$, if $V_i \cdot \hat{x}$ is positive and $V_{i+1} \cdot \hat{x}$ is negative (or the opposite), we will go through the non-saturated zone, in which gradients on $V_i$ and $V_{i+1}$ flow well compared to ordinary neural networks. This might yield easier optimization of input-to-hidden weights, even though their value is large.
3 Non-Parametric Continuous Neural Networks

This section returns on the strong link between kernel methods and continuous neural networks, first presented in (Neal, 1994). It also exhibits a clear connection with Gaussian processes, with a newly motivated kernel formula. Here, we start from eq. 2 but use as an index $u$ the elements of $\mathbb{R}^{d+1}$ themselves, i.e. $V$ is completely free and fully non-parametric: we integrate over all possible weight vectors.

To make sure that the integral exists, we select a set $E$ over which to integrate, so that the formulation becomes

$$f(x) = \int_{E} a(u)g(x \cdot u) \, du$$

$$= \langle a, g_x \rangle$$

(8)

(9)

with $\langle , \rangle$ the usual dot product of $\mathcal{L}^2(E)$ and $g_x$ the function such that $g_x(u) = g(x \cdot u)$.

3.1 $\mathcal{L}^1$-norm Output Weights Regularization

Although the optimization problem becomes convex when the $\mathcal{L}^1$-norm of $a$ is penalized, it involves an infinite number of variables. However, we are guaranteed to obtain a finite number of hidden units with non-zero output weight, and both exact and approximate optimization algorithms have been proposed for this case in (Bengio et al., 2005). Since this case has already been well treated in that paper, we focus here on the $\mathcal{L}^2$ regularization case.

3.2 $\mathcal{L}^2$-norm Output Weights Regularization

In some cases, we know that the optimal function $a$ can be written as a linear combination of the $g_x$, with the $x_i$’s the training examples. For example, when the cost function is of the form

$$c((x_1, y_1, f(x_1)), ..., (x_m, y_m, f(x_m))) + \Omega(\|f\|_{\mathcal{H}})$$

with $\|f\|_{\mathcal{H}}$ is the norm induced by the kernel $k$ defined by $k(x_i, x_j) = \langle g_{x_i}, g_{x_j} \rangle$, we can apply the representer theorem (Kimeldorf and Wahba, 1971).
It has been known for a decade that, with Gaussian priors over the parameters, a neural network with a number of hidden units growing to infinity converges to a Gaussian process (chapter 2 of (Neal, 1994)). However, Neal did not compute explicitly the covariance matrices associated to specific neural network architectures. Such covariance functions have already been analytically computed (Williams, 1997), for the cases of sigmoid and Gaussian transfer functions. However, this has been done using a Gaussian prior on the input-to-hidden weights. The formulation presented here corresponds to a uniform prior (i.e. with no arbitrary preference for particular values of the parameters) when the transfer function is sign. The sign function has been used in (Neal, 1994) with a Gaussian prior on the input-to-hidden weights, but the explicit covariance function could not be computed. Instead, approximating locally the Gaussian prior with a uniform prior, Neal ended up with a covariance function of the form $k(x, y) ≈ A - B||x - y||$. We will see that, using a uniform prior, this is exactly the form of kernel one obtains.

3.3 Kernel when $g$ is the sign Function

**Theorem 4.** A neural network with an uncountable number of hidden units, a uniform prior over the parameters and a sign transfer function is a Gaussian process whose kernel is of the form

$$k(x_i, x_j) = 1 - C||x_i - x_j||$$

Such a kernel can be made hyperparameter-free for kernel regression, kernel logistic regression or SVMs.

The proof is provided in the Appendix.

3.3.1 Function sampling

As presented in (Neal, 1994), the functions generated by this Gaussian process are Brownian (see figure 3). Contrary to other transfer functions and frameworks, this covariance function does not have any hyperparameter. Indeed, the solution is invariant if the covariance function is modified by adding a constant to $k(x, y)$, since the optimal solution for kernel regression or SVM is a weight vector whose elements sum to 0. Moreover, changing the covariance function by a multiplicative factor is equivalent to accordingly multiply the weight decay on the output weights. It is also possible to set a weight decay equal to 0. The problem becomes ill-defined as many vectors yield a cost of 0. However, all solutions lead to the same function. This setting suppresses the remaining hyperparameter for the sign kernel (a more detailed explanation is in the appendix).
3.3.2 Experiments on the USPS dataset

We tried this new hyper-parameter free kernel machine on the USPS dataset, with quadratic training cost.

Table 1: sign kernel vs Gaussian kernel on USPS dataset with 7291 training samples, with different Gaussian widths $\sigma$ and weight decays $\lambda$. For each kernel, the best value is in bold. The star indicates the best overall value. The first three columns are validation error ± standard deviation. The last one is the test error.

To evaluate the stability of the sign kernel, we compared it with the Gaussian kernel on the USPS dataset. We optimized the hyperparameters of the Gaussian kernel on the test set (optimization on the validation set yields 4.0% test error). As there are no hyperparameters for the sign kernel, this clearly is in favor of the Gaussian kernel. We can see in table 1 that the Gaussian kernel is much more sensitive to hyperparameters, whereas the performance of the sign kernel is the same for $\lambda$ varying from $10^{-3}$ to 0. We show the mean and the standard deviation of the error over 10 runs.

3.3.3 LETTERS dataset

Similar experiments have been performed on the LETTERS dataset. Again, whereas the sign kernel does not get the best overall result, it performs comparably to the best Gaussian kernel (see table 2).

3.4 Conclusions, Discussion, and Future Work

We have studied in detail two formulations of uncountable neural networks, one based on a finite parametrization of the input-to-hidden weights, and one that is fully non-parametric. The first approach delivered a number of interesting results: a new function approximation theorem, an affine parametrization in which the integrals can be computed analytically, and an error bound theorem that suggests better approximation properties than ordinary neural networks.

As shown in theorem 1, function $V$ can be represented as $d + 1$ functions from $\mathbb{R}$ to $\mathbb{R}$, easier to learn than one function from $\mathbb{R}^{d+1}$ to $\mathbb{R}$. We did not find parametrizations of those functions other than the continuous piecewise affine one with the same feature of analytic integration. To obtain smooth functions $V$ with restricted complexity, one could set the functions $V$ to be outputs of another neural network taking a discrete index in argument. However, this has not yet been exploited and will be explored in future work.

The second, non-parametric, approach delivered another set of interesting results: with sign activation functions, the integrals can be computed analytically, and correspond to a hyperparameter-free kernel machine that yields performances comparable to the Gaussian kernel. These results raise a fascinating question: why are results with the sign kernel that good with no hyper-parameter and no regularization? To answer this, we should look at the shape of the covariance function $k(x, y) = 1 - C||x - y||$, which suggests the following conjecture: it can discriminate between neighbors of a training example while being influenced by remote examples, whereas the Gaussian kernel does either one or the other, depending on the choice of $\sigma$.

References

Appendix: Proofs of the Theorems

In all the following proofs, we will define the function $\phi_{V,\alpha,\beta}$ by

$$\phi_{V,\alpha,\beta} = x \mapsto \beta + \alpha \int_0^1 \tanh (V(z) \cdot x) \, dz$$

Lemma 1. When $V$ is a piecewise-constant function such that

$$V(z) = V_i \quad \text{when} \quad p_{i-1} \leq z < p_i$$

with $a_0 = 0$, $\alpha = \sum_i a_i$ and $p_i = \frac{1}{\alpha} \sum_{j=0}^i a_j$, we have

$$\beta + \alpha \int_0^1 g[\tilde{x} \cdot V(z)] \, dz = \beta + \sum_i a_i g(\tilde{x} \cdot V_i) \quad (10)$$

Proof.

$$\beta + \alpha \int_0^1 g[\tilde{x} \cdot V(z)] \, dz = \beta + \alpha \sum_i \int_{p_{i-1}}^{p_i} g[\tilde{x} \cdot V(z)] \, dz$$

$$= \beta + \alpha \sum_i \int_{p_{i-1}}^{p_i} g(\tilde{x} \cdot V_i) \, dz$$

$$= \beta + \alpha \sum_i (p_i - p_{i-1}) g(\tilde{x} \cdot V_i)$$

$$= \beta + \alpha \sum_i \frac{a_i}{\alpha} g(\tilde{x} \cdot V_i)$$

$$= \beta + \sum_i a_i g(\tilde{x} \cdot V_i)$$

Theorem 1. Any Borel measurable function $f$ from $K$ compact of $\mathbb{R}^d$ to $\mathbb{R}$ can, with an arbitrary precision, be defined by $d + 1$ functions $V^i$ from $[0, 1]$ to $\mathbb{R}$ and two reals $\alpha$ and $\beta$ with the relation

$$f(x) = \beta + \alpha \int_0^1 \tanh \left( \sum_{i=1}^{d} V^i(z) \cdot x_i + V^{n+1}(z) \right) \, dz$$

Proof. Let $f$ be an arbitrary Borel Measurable function on a compact set $K$ and $\varepsilon > 0$. By the universal approximation theorem (Hornik, Stinchcombe and White, 1989), we know that there are input weights $v_i, i = 1, \ldots, n$, output weights $a_i, i = 1, \ldots, n$ and an output bias $b$ such that

$$\sup_{x \in K} \left| f(x) - b - \sum_{i=1}^{n} a_i \tanh(v_i \cdot x) \right| < \varepsilon$$
By optionally replacing \( v_i \) by \(-v_i\), we can restrict all the \( a_i \) to be positive. Defining \( \alpha = \sum_i a_i \) and \( V \) such that \( V(z) = v_i \) if \( \frac{\sum_{i=1}^{j-1} a_i}{\alpha} \leq z < \frac{\sum_{i=1}^{j} a_i}{\alpha} \), we have

\[
\sup_{x \in K} \left| f(x) - b - \int_{z=0}^{1} \tanh (V(z) \cdot x) \, dz \right| < \varepsilon
\]

Therefore, for all \( \varepsilon > 0 \), there exists a function \( V \) from \([0, 1]\) to \( \mathbb{R}^{d+1} \) and two reals \( \alpha \) and \( \beta \) such that \( \sup_{x \in K} |f(x) - \phi(V, \alpha, \beta)| < \varepsilon \).

But as \( V \) can be decomposed in \( d + 1 \) functions from \([0, 1]\) to \( \mathbb{R} \), any Borel measurable function \( f \) can, with an arbitrary precision, be defined by

- \( d + 1 \) functions from \([0, 1]\) to \( \mathbb{R} \)
- two scalars \( \alpha \) and \( \beta \).

\[ \Box \]

**Theorem 2.** \( \forall x, \forall V^*, \forall \alpha^*, \forall \beta^*, \forall V \), we have

\[
|\phi_{V, \alpha^*, \beta^*}(x) - \phi_{V^*, \alpha^*, \beta^*}(x)| \leq 2\alpha^* \int_{z=0}^{1} \tanh \left( |(V(z) - V^*(z)) \cdot \tilde{x}| \right) \, dz
\]

**Proof.**

\[
|\phi(V, \alpha^*, \beta^*)(x) - f^*(x)| = |\alpha^*| \left| \int_{z=0}^{1} (\tanh [V(z) \cdot \tilde{x}] - \tanh [V^*(z) \cdot \tilde{x}]) \, dz \right|
\]

\[
= |\alpha^*| \left| \int_{z=0}^{1} \tanh [(V(z) - V^*(z)) \cdot \tilde{x}] (1 - \tanh [V(z) \cdot \tilde{x}] \tanh [V^*(z) \cdot \tilde{x}]) \, dz \right|
\]

\[
\leq |\alpha^*| \int_{z=0}^{1} |\tanh [(V(z) - V^*(z)) \cdot \tilde{x}]| \, dz \times \sup_{z} |1 - \tanh [V(z) \cdot \tilde{x}] \tanh [V^*(z) \cdot \tilde{x}]| < 2.
\]

Thus,

\[
|\phi(V, \alpha^*, \beta^*)(x) - f^*(x)| \leq 2|\alpha^*| \int_{z=0}^{1} |\tanh [(V(z) - V^*(z)) \cdot \tilde{x}]| \, dz
\]

\[
|\phi(V, \alpha^*, \beta^*)(x) - f^*(x)| \leq 2|\alpha^*| \int_{z=0}^{1} \tanh ||(V(z) - V^*(z)) \cdot \tilde{x}| | \, dz
\]

(11)

\[ \Box \]

**Theorem 3.** Let \( f^* = \phi_{V^*, \alpha^*, \beta^*} \) with \( V^* \) a function with a finite number of discontinuities and \( C^1 \) on each interval between two discontinuities. Then there exists a scalar \( C \), a piecewise affine continuous function \( V \) with \( h \) pieces and two scalars \( \alpha \) and \( \beta \) such that, for all \( x \), \( |\phi_{V, \alpha, \beta}(x) - f^*(x)| \leq Ch^{-2} \) (pointwise convergence).
\textit{Proof.} Let \( V^* \) be an arbitrary continuous function on \([p_{i-1}, p_i]\). Then, choosing the constant function \( V : z \mapsto \frac{V^*(p_{i-1}) + V^*(p_i)}{2} \) yields for all \( z \) in \([p_{i-1}, p_i]\):

\[
|V^*(z) - V(z)| \leq \frac{p_i - p_{i-1}}{2} M_1(V^*, [p_{i-1}, p_i])
\]

(12) where \( M_1(V, I) = \max_{z \in I} |V'(z)| \) (\( M_1(V, I) \) is the maximum absolute value of the first derivative of \( V \) on the interval \( I \)).

Now let \( V^* \) be a function in \( C^1 \) (that is, a function whose derivative is continuous everywhere) and choose the affine function \( V : z \mapsto V^*(p_{i-1}) + \frac{z - p_{i-1}}{p_i - p_{i-1}} (V^*(p_i) - V^*(p_{i-1})) \). The trapezoid method tells us that the following inequality is verified:

\[
|V^*(z) - V(z)| \leq \frac{(z - p_{i-1})(p_i - z)}{2} M_2(V^*, [p_{i-1}, p_i])
\]

where \( M_2(V, I) = \max_{z \in I} |V''(z)| \) (\( M_2(V, I) \) is the maximum absolute value of the second derivative of \( V \) on the interval \( I \)). Using the fact that, for all \( z \) in \([p_{i-1}, p_i]\), \((z - p_{i-1})(p_i - z) \leq \frac{(p_i - p_{i-1})^2}{4}\), we have

\[
|V^*(z) - V(z)| \leq \frac{(p_i - p_{i-1})^2}{8} M_2(V^*, [p_{i-1}, p_i])
\]

(13)

Besides, theorem 2 states that

\[
|\phi(V, \alpha^*, \beta^*)(x) - \phi(V^*, \alpha^*, \beta^*)(x)| \leq 2|\alpha^*| \int_{z=0}^{1} \tanh \left(|(V(z) - V^*(z)) \cdot \tilde{x}|\right) dz
\]

But

\begin{itemize}
  \item \( \int_{z=0}^{1} \tanh \left(|(V(z) - V^*(z)) \cdot \tilde{x}|\right) dz \leq \sup_{[0,1]} \tanh \left(|(V(z) - V^*(z)) \cdot \tilde{x}|\right) \)
  \item \( \tanh \left(|(V(z) - V^*(z)) \cdot \tilde{x}|\right) \leq |(V(z) - V^*(z)) \cdot \tilde{x}| \)
\end{itemize}

Thus,

\[
|\phi(V, \alpha^*, \beta^*)(x) - \phi(V^*, \alpha^*, \beta^*)(x)| \leq 2|\alpha^*| \sup_{[0,1]} |(V(z) - V^*(z)) \cdot \tilde{x}| 
\]

(14)

\[
|\phi(V, \alpha^*, \beta^*)(x) - \phi(V^*, \alpha^*, \beta^*)(x)| \leq 2|\alpha^*| \sup_{[0,1]} |(V(z) - V^*(z)) \cdot \tilde{x}| 
\]

\[
\leq 2|\alpha^*| \sup_{[0,1]} \left| \sum_i x_i (V_i(z) - V_i^*(z)) \right| 
\]

\[
\leq 2|\alpha^*| \sum_i |x_i| \sup_{[0,1]} |V_i(z) - V_i^*(z)| 
\]

In the case of a piecewise constant function, this inequality becomes:

\[
|\phi(V, \alpha^*, \beta^*)(x) - \phi(V^*, \alpha^*, \beta^*)(x)| \leq 2|\alpha^*| \sum_i |x_i| \sup_{j} \frac{p_j - p_{j-1}}{2} M_1(V_i^*, [p_{j-1}, p_j]) 
\]

\[
|\phi(V, \alpha^*, \beta^*)(x) - \phi(V^*, \alpha^*, \beta^*)(x)| \leq |\alpha^*| M_1(V^*, [0,1]) \sum_i |x_i| \sup_{j} (p_j - p_{j-1}) 
\]

(15)
In the case of a piecewise affine function, this inequality becomes:

\[
|\phi(V, \alpha^*, \beta^*)(x) - \phi(V^*, \alpha^*, \beta^*)(x)| \leq 2|\alpha^*| \sum_i |x_i| \sup_j \frac{(p_j - p_{j-1})^2}{8} M_2(V^*_i, [p_{j-1}, p_j])
\]

\[
|\phi(V, \alpha^*, \beta^*)(x) - \phi(V^*, \alpha^*, \beta^*)(x)| \leq \frac{|\alpha^*| M_1(V^*_i, [0, 1])}{4} \sum_i |x_i| \sup_j (p_j - p_{j-1})^2 \tag{16}
\]

If \( V^* \) has a \( k \) discontinuities and \( V \) has \( h \) pieces (corresponding to a neural network with \( h \) hidden neurons), we can place \( p_{d,i} \) at the \( i \)-th discontinuity and split each interval between two discontinuities into \( \frac{h}{k} \) pieces. The maximum value of \( p_j - p_{j-1} \) is thus lower than \( \frac{k}{h} \) (since the \( p_j \) are between 0 and 1).

We thus have the following bounds:

\[
|\phi(V_C, \alpha^*, \beta^*)(x) - \phi(V^*, \alpha^*, \beta^*)(x)| \leq \frac{C_2}{h} \tag{17}
\]

\[
|\phi(V_A, \alpha^*, \beta^*)(x) - \phi(V^*, \alpha^*, \beta^*)(x)| \leq \frac{C_2}{h^2} \tag{18}
\]

where \( V_C \) is a piecewise constant function and \( V_A \) is a piecewise affine function. \( C_1 \) and \( C_2 \) are two constants (the \( x_i \) are bounded since we are on a compact).

This concludes the proof. \( \square \)

**Theorem 4.** A neural network with an uncountable number of hidden units, a uniform prior over the parameters and a sign transfer function is a Gaussian process whose kernel is of the form

\[
k(x, y) = 1 - C ||x - y||
\]

Besides, such a kernel can be made hyperparameter-free for kernel linear regression, kernel logistic regression or SVM.

**Proof.** For the sake of shorter notation, we will denote the sign function by \( s \) and warn the reader not to get confused with the sigmoid function.

We wish to compute

\[
k(x, y) = \langle g_x, g_y \rangle = E_{v,b} [s(v \cdot x + b)s(v \cdot y + b)]
\]

Since we wish to define a uniform prior over \( v \) and \( b \), we cannot let them span the whole space (\( \mathbb{R}^n \) in the case of \( v \) and \( \mathbb{R} \) in the case of \( b \)). However, the value of the function sign does not depend on the norm of its argument, so we can restrict ourselves to the case where \( ||v|| = 1 \). Furthermore, for values of \( b \) greater than \( \delta \), where \( \delta \) is the maximum norm among the samples, the value of the sign will be constant to 1 (and -1 for opposite values of \( b \)). Therefore, we only need to integrate \( b \) on the range \([-\delta, \delta]\).

Defining a uniform prior on an interval depending on the training examples seems contradictory. We will see later that, as long as the interval is big enough, its exact value does not matter.

Let us first consider \( v \) fixed and compute the expectation over \( b \). The product of two sign functions is equal to 1 except when the argument of one sign is positive and the other negative. In our case, this becomes:

\[
\begin{align*}
v \cdot x + b &< 0 \quad \text{or} \quad v \cdot x + b > 0 \\
v \cdot y + b &> 0 \\
v \cdot y + b &< 0
\end{align*}
\]
which is only true for $b$ between $-\min(v \cdot x, v \cdot y)$ and $-\max(v \cdot x, v \cdot y)$, which is an interval of size $|v \cdot x - v \cdot y| = |v \cdot (x - y)|$. Therefore, for each $v$, we have

$$E_b[s(v \cdot x + b)s(v \cdot y + b)] = \frac{(2\delta - 2|v \cdot (x - y)|)}{2\delta} = 1 - \frac{|v \cdot (x - y)|}{\delta}.$$ 

We must now compute

$$k(x, y) = 1 - E_v \left[ \frac{|v \cdot (x - y)|}{\delta} \right]$$  \hspace{1cm} (19)

It is quite obvious that the value of the second term only depends on the norm of $(x - y)$ due to the symmetry of the problem. The value of the kernel can thus be written

$$k(x, y) = 1 - C||x - y||$$  \hspace{1cm} (20)

Writing $k(x, y) = 1 - C||x - y||$, we have

$$C = \frac{1}{S(d, 1)} \int_{v/\|v\|=1} |v \cdot (x - y)|/||x - y|| \, dv \hspace{1cm} = \frac{2}{\delta S(d, 1)} \int_0^{\pi/2} \cos(\theta)S(d-1, \sin(\theta)) \, d\theta \hspace{1cm} = \frac{2S(d-1, 1)}{\delta S(d, 1)(d-1)}$$

where $S(d, r)$ is the surface of the hypersphere $S_d$ of radius $r$ and $d$ is the dimensionality of the data. Therefore,

$$k(x, y) = 1 - \frac{2S(d-1, 1)}{\delta S(d, 1)(d-1)} ||x - y||$$

Then, noticing that $\sqrt{\frac{d-1}{2\pi}} < \frac{S(d-1, 1)}{S(d, 1)} < \sqrt{\frac{d}{2\pi}}$, we have $\frac{1}{\delta} \sqrt{\frac{2}{\pi(d-1)}} < \frac{2S(d-1, 1)}{\delta S(d, 1)(d-1)} < \frac{\sqrt{2d}}{\delta(d-1)\pi}$.

As we could have integrated over a slightly larger integral than the minimum required, we can set our kernel function to be

$$k(x, y) = 1 - \frac{\sqrt{2}}{\delta \sqrt{(d-1)\pi}} ||x - y||$$  \hspace{1cm} (21)

with $d$ the dimensionality of the data and $\delta$ the maximum $L^2$-norm among the samples. The coefficient in front of the term $||x - y||$ has a slightly different form when $d = 1$ or $d = 2$.

Let us now denote by $K$ the matrix whose element $(i, j)$ is $K(x_i, x_j)$. The solution in kernel logistic regression, kernel linear regression and SVM is of the form $K\alpha$ where $\alpha$ is the weight vector. It appears that the weight vector is orthogonal to $e = [11 \ldots 1]'$. 

15
Thus, adding a constant value $c$ to every element of the covariance matrix changes the solution from $K\alpha$ to $(K + cee')\alpha = K\alpha + ee'\alpha = K\alpha$.

Therefore, the covariance matrix is defined to an additive constant.

Besides, in kernel logistic regression, kernel linear regression and SVM, the penalized cost is of the form

$$C(K, \lambda, \alpha) = \mathcal{L}(K\alpha, Y) + \lambda\alpha'K\alpha$$

We can see that $C(K, \lambda, \alpha) = C(cK, c\lambda, \frac{\alpha}{c})$. Thus, multiplying the covariance matrix by a constant $c$ and the weight decay by the same constant yields an optimal solution $\alpha^*$ divided by $c$. However, the product $K\alpha$ remains the same.

In our experiments, the value of the weight decay had very little influence. Furthermore, the best results have always been obtained for a weight decay equal to 0. This means that no matter the multiplicative factor by which $K$ is multiplied, the result will be the same.

This concludes the proof that this kernel can be made hyperparameter-free.
